KEYWORDS Tumour Response. Comet Assay.

ABSTRACT The present study has been carried out to evaluate tumour response to the multi-modalities of treatment using comet assay in breast cancer patients and to assess the efficacy of combinatorial therapy over single modality treatments. An effort was also made to correlate the extent of DNA damage with the cycles of chemotherapy given. A positive correlation was found with the selected comet parameters.

INTRODUCTION

The ability of surgical oncologists, medical oncologists and radiation oncologists to develop multi-disciplinary treatment plans for individual patients has served as an important tool for effective cancer management strategies Chan et al. (2006).

Response to treatment varies with stage, age, pathological condition and economic status of the patient Muss et al. (2000). Treatments are generally judged to be effective if they produce either a complete or a partial remission. A patient's responsiveness to therapy usually is determined after two to three months of the treatment. The patient's description of symptoms also plays an important role. In addition, it is important to note that there is an inter individual variability in response to therapy among patients Lou et al. (2005).

If tumour sensitivity could be predicted in advance, it may be possible to improve control rates significantly by selecting the therapy to which the tumour respond. This will help reduce the side effects for the individual patient.

Many of the patients undergoing one treatment fail to respond, and there are high chances for tumour to establish and also consequently crucial time goes waste for some ineffectual therapies Nicole et al. (2008).

If there is a possibility to assess the response

rate before the crucial time reaches, it will be highly beneficial to implement an effective treatment option for patient. To assess the response, the use of the comet assay, which shows the extent of DNA damage in the peripheral lymphocytes Nadin et al. (2006), may help in the earlier identification of patients not responding to the therapy and suggests suitable therapies within the crucial time limits. The present study is undertaken to judge the treatment by comparing the efficacy of different modalities of treatment with respect to DNA damage.

MATERIALS AND METHODS

Study Population

The study was carried out on locally advanced breast cancer patients (LABC) from a hospital at Chennai. They were asked to complete a self-administered questionnaire containing details of reproductive history, medical conditions, family history and treatment conditions. Among the total of 41 subjects five were found to have distant metastasis and only one with the family history of breast cancer (Table 1). All the patients with LABC were undergoing different modalities of treatment, i.e., chemotherapy alone (n=12), chemotherapy + surgery (n=10), chemotherapy + radiotherapy

*-One with family history of breast cancer.

(n=8) and chemotherapy + surgery + radiotherapy (n=11).

A total number of 17 healthy individuals who had no history of any type of cancer served as control subjects (age ranges from 30-60years).

Comet Assay

A few μ l of heparinised blood was collected from each subject. Each blood sample was suspended in RMPI 1640 medium with 20% fetal calf serum and were incubated for 30 min at 37°C. The method of SCGE technique was followed Singh et al. (1998). In brief, blood samples after incubation were suspended in low melting

agarose (0.5%) and were layered on freshly frosted slides between regular agarose (0.75%) and low melting agarose (0.5%). The slides were left overnight at 4°C in cold lysing solution with high salt concentrations (1% Sodium Lauryl sarcosinate, 2.5M NaCl, 100mM Na₂EDTA; 1% Triton X 100 and 10% DMSO were added just before use and pH adjusted to 10. Slides were then given alkali treatment (1mM Na₂EDTA, 300 mM NaOH) for 20 minutes at pH 10 and then subjected to electrophoresis at 300 milli Amps and 20 Volts in the same buffer for additional 20 minutes. All the above steps were conducted in yellow light to prevent additional exogenous DNA damage. Following electrophoresis, the slides were rinsed into neutralizing buffer and stained with silver stain, sealed with coverslip.

Evaluation of DNA Damage

The cells were scored according to the degree of damage or the migration of DNA from cells after electrophoresis. For each sample at least 50 cells were scored randomly and the slides were observed at 40x objective magnification.

The frequency of intact cells, cells with short tails, cells with medium, and cells with long tails were scored.

According to their tail length cells were categorized into Type I, Type II and Type III. DNA damage was quantified for each cell by measuring the total length (head to tail).

To assess the efficacy of a particular treatment option, the data obtained for each treatment group was subjected to ANOVA. Correlation analysis was performed to assess the relationship of age of the patients Vs DNA damage and cycles of chemotherapy Vs DNA damage. Chi-square test was used for finding significance of DNA damage with respect to the parity.

RESULT AND DISCUSSION

The level of DNA damage showed variance in each therapy showing the responsiveness of the tumour. It was observed that the combinatorial modality (chemotherapy + surgery + radiotherapy) was the most effective over the single modality of treatment, i.e., chemotherapy alone. The data interpreted in combinatorial modality showed a reduced tail length and less number of damaged cells (Table 2), Type I, Type II and Type III, while the values for the same

parameters were found to be higher in the patients undergoing other modalities, namely, chemotherapy +radiotherapy, chemotherapy + surgery and chemotherapy alone respectively.

The present study reported a consistent association between DNA damage and different modalities of treatments. The association was most strongly indicated by reduced values of comet parameters when the locally advanced breast cancer patients opted for chemotherapy + surgery + radiotherapy showing the significance of combined modalities.

Natsugoe et al. (2006) in their study of recurrence of oesophageal squamous cell cancer, found a significant survival rate from recurrence to mortality in patients who underwent surgery + other therapy (6.7%) in comparison to no survival in patients undergone chemotherapy alone (0%) equal to the patients without any treatment. The above finding shows relevance of present study which reported limitation of chemotherapy alone in comparison to combined therapy viz. chemotherapy + surgery + radiation therapy.

The study has shown a comparatively high DNA damage in patients undergoing the chemotherapy alone, showing the limitations of using single modality of the treatment. Halder et al. (2002) also observed severe degree of damage of DNA at the relapsed stage of post chemotherapy induced patients with little or no immature cells seen in peripheral blood and bone marrow, supporting a short term benefits of chemotherapy alone.

Wolf et al. (1991) also demonstrated that there is no significant difference in survival between patients having induction chemotherapy and

radiation verses surgery and radiation in respectable advanced stages squamous cell carcinoma of the larynx. However, the larynx was preserved in 64% of the patients who received induction chemotherapy and radiation therapy. This data supports the idea of initial chemotherapy followed by radiation, instead of surgical management of the tumour. In our study, the tumour response to chemotherapy + radiotherapy was higher than that of chemotherapy + surgery thereby, it suggests conservation of breast tissue by avoiding surgery.

An attempt was made to compare the DNA damage profile with the age of the patients irrespective of the cycles of chemotherapy. A positive correlation was observed between age of the patients and the DNA damage (Table 3). It was found that DNA damage is more in older patients as compared with younger patients.

The above findings corroborate with the study of Deffaud et al. (1997) and Peace and Succop(1999) who observed an increase in the frequency of affected cells with aging. This could be attributed to the accumulation of genetic damage in the cells or to the aging process, such

Table 3: Correlation between extent of DNA damage and age of the patients / chemotherapy cycles

<i>Parameters</i>	<i>Age of the patients</i>	<i>Chemotherapy cycles</i>
Tail length (mm)	+ 0.012	- 0.112
No. of damaged cells/ 50 cells	+ 0.10	- 0.088
Head - tail ratio	+ 0.014	+ 0.060
Type - I	- 0.326	+ 0.327
Type - II	+ 0.197	- 0.27
Type - III	- 0.064	- 0.066

as altered cellular metabolism and decrease in the efficiency of DNA repair.

An American study by Singh et al. (1991) detected a 12% increase in the basal level of DNA damage among individuals of above 60 years of age compared with individuals of below 60 years, which was ascribed to a 5 fold higher content of highly damaged cells among older individuals.

A negative correlation was found between cycles of chemotherapy and comet parameters (Table 4). When the cycles of chemotherapy goes up these patients showed less DNA damage as compared to the initial cycles of chemotherapy, which indicates that the tumour is responding well to the chemotherapy. In some cases, it is not so because they are not responding to the chemotherapy.

Table 4: Head-tail ratio (>1mm and <1mm) of parous and Nulliparous samples studied

Head - Tail Ratio	> 1 mm	< 1 mm	Total
Parous	36	16	52
Nulliparous	7	2	9
Total	43	18	61

$\chi^2 = 0.268$; $p < 0.05$

Data pertaining to parity was interpreted and presented in Table 4 for DNA damage studies in patients and controls. The samples with nulliparity (n=9) and parity (n=52) were grouped according to the damage profile (head to tail ratio) above 1µm and below 1µm, irrespective of the stage, age and treatment option. The results were insignificant, indicating that parity may not affect the DNA.

In conclusion it may be stated, if comet assay is carried out after three cycles of chemotherapy with a baseline comet assay before starting the next cycles of chemotherapy, the tumour responses can be assessed at the molecular level thereby to suggest a change in the modality of treatment as per the results. The present study although a preliminary, plays an important role in deciding the modality of treatment thereby enhances the recovery rates.
